Watchful waiting for small non-functional pancreatic neuroendocrine tumours: nationwide prospective cohort study (PANDORA)

Introduction

Non-functional pancreatic neuroendocrine tumours (NF-pNETs) are rare neoplasms, often detected incidentally. The prognosis varies and is largely dependent on the Ki-67 proliferation index, presence of a genetic syndrome, lymph node involvement, and tumour size 1–4. Resection of pancreatic lesions is associated with significant morbidity, and may include long-term complications such as new-onset diabetes and exocrine pancreatic insufficiency 5,6. Clearly, the potential survival benefit obtained with surgery needs to outweigh the morbidity associated with pancreatic surgery. This explains the current controversy regarding small (2 cm or less) asymptomatic NF-pNETs, for which some advocate surgery and others suggest a conservative approach 7–11.

Based on retrospective data, guidelines advise watchful waiting for NF-pNETs of 2 cm or smaller, but provide no clear recommendation on the required follow-up 8,12. Therefore, the objective of this study was to prospectively evaluate disease-related outcomes and quality of life (QoL) after implementation of a nationwide, watchful-waiting programme for NF-pNETs no larger than 2 cm. The study also sought to evaluate the feasibility of the proposed follow-up protocol, as well as adherence to the protocol in participating centres.

Methods

This was an interim analysis of the multicentre prospective PANDORA study of the Dutch Pancreatic Cancer Group. Full details of the study design, methods employed, and statistical analysis can be found in Appendix S1. All patients with sporadic, asymptomatic NF-pNETs of 2 cm or smaller were included if they met the eligibility criteria, in particular absence of nodal and/or distant metastases. The trial was registered in the Netherlands Trial Register (NL6510).

Patients were enrolled into a watchful-waiting protocol to monitor tumour progression (Fig. 1). Surgical resection was recommended if patients developed symptoms, tumour growth exceeding 0.5 cm/year, total tumour size greater 2 cm, pathological lymph node enlargement, vascular involvement or infiltration into surrounding organs, or pancreatic duct dilatation, or if the patient expressed a strong preference for operation.

Results

Between 1 January 2017 and 29 February 2020, a total of 76 patients with a NF-pNET no larger than 2 cm were included. Baseline characteristics are summarized in Table S1. During a median follow-up of 17 (i.q.r. 8–35) months, 68 participants (89 per cent) had no signs of tumour progression. Eight patients (11 per cent) showed tumour progression exceeding 0.5 cm/year, and two also had a final tumour size of more than 2.0 cm. No other tumours larger than 2.0 cm were noted, and 21 patients (28 per cent) had tumours smaller than 1.0 cm. Characteristics of patients with progression are shown in Table 1 and Table S1.

Overall, six patients (8 per cent) underwent surgery during follow-up (Table S2). Two patients had surgery because of significant tumour growth, detected after 3 and 10 months of follow-up. One patient had tumour progression of 0.8 cm in 1 year (from 1.8 to 2.6 cm). Gallium-68 DOTATATE PET–CT showed two enlarged lymph
nodes (aortocaval and para-aortal). During surgery, one unexpected peritoneal deposit was identified and the patient underwent laparoscopic enucleation of the primary tumour with lymphadenectomy and removal of the peritoneal lesion. The final histopathological diagnosis was a pNET of 2.0 cm, with a Ki-67 index of 5–10 per cent, two positive lymph nodes and, indeed, peritoneal metastasis. Two new lymph nodes were detected 11 months after surgery, for which somatostatin analogue therapy was started.

The second patient showed tumour progression exceeding 0.5 cm (from 1.0 to 1.7 cm) within 3 months of follow-up and as a result underwent surgery. The final histopathological diagnosis showed a pNET of 1.7 cm, R0 resection, with a Ki-67 index of less than 3 per cent, and 0 of 17 positive lymph nodes. The patient is currently asymptomatic at 11 months’ follow-up without signs of disease progression.

Three patients had a pNET resected despite lacking an indication according to the study protocol. Of these, two underwent spleen-preserving distal pancreatectomy, citing fear of disease progression as the predominant reason for requesting surgery. One patient underwent laparoscopic spleen-preserving distal pancreatectomy because the surgeon did not support the decision for watchful waiting and advocated tumour resection. All three patients had a pNET on final histopathology.

A fourth patient had a pNET enucleated owing to uncertainty regarding the pNET diagnosis on delayed (contrast-enhanced) endoscopic ultrasonography (EUS) at 8 months’ follow-up. The final histopathological report showed an intravascular pyogenic granuloma, but no pNET.

In total, four patients died, all from non-pNET-related causes.

Although the study protocol recommended confirmation of the diagnosis to by at least 2 different imaging modalities, only one type of imaging was used at the time of diagnosis in 19 patients (25 per cent). Thirty-two patients (42 per cent) had two, and 25 (33 per cent) had three or more imaging modalities to confirm the diagnosis. Only 17 patients (22 per cent) underwent EUS at the suggested 3-month time point. Instead, patients opted for CT (31, 41 per cent), MRI (16, 21 per cent), or no imaging at all (12, 16 per cent). At 6 and 12 months, 21 (28 per cent) and 11 (15 per cent) patients did not undergo any imaging.

Qol scores on the European Organisation for Research and Treatment of Cancer QLQ-C30 questionnaire were statistically significantly worse at baseline for the study population compared with the mean of the reference population regarding emotional functioning (83.9 versus 89.0; \( P = 0.042 \)), nausea and vomiting (6.9 versus 2.7; \( P = 0.037 \)), dyspnoea (18.8 versus 7.1; \( P = 0.004 \)), and insomnia (22.9 versus 14.0; \( P = 0.046 \)) (Fig. S1).

**Discussion**

This multicentre prospective cohort study, which evaluated watchful waiting for NF-pNETs no larger than 2 cm, found that
short-term follow-up is both safe and feasible. A small proportion of patients showed tumour progression. Application of a watchful-waiting protocol successfully prevented surgery in over 9 of 10 patients. Furthermore, heterogeneity in pNET management, despite use of a study protocol, was observed in this study, along with poor QoL at the time of diagnosis.

The present finding of slow tumour progression supports previous studies5,11,13–17 of NF-pNETs of 2 cm or smaller, which advised wait-and-see in certain patients. In contrast, other authors18 have recommended upfront surgery for all pNETs, as even small lesions may have malignant characteristics that could impair survival. Importantly, patients with malignant tumour features were excluded from the present study, and, even when significant tumour growth occurred, six of eight patients with tumour progression refused surgery and opted to continue watchful waiting. Collectively, these results indicate that, under strict criteria, patients with a NF-pNET no larger than 2 cm can safely be treated conservatively.

In turn, it is clear that implementation of this novel watchful-waiting approach to pNET is challenging19–21. As is common in investigator-driven multicentre studies, not all centres adhered strictly to the follow-up protocol. EUS was included at 3 and 12 months of follow-up to reduce the number of scans per patient, and so that multiple imaging modalities could confirm tumour size stability. It also provided an immediate opportunity to perform fine-needle aspiration (FNA) if there was doubt regarding tumour origin. However, EUS was considered a high burden for patients, and was frequently rejected by both patients and physicians. In addition, not all patients underwent the suggested CT or MRI at 6 and 12 months’ follow-up, as the interval after diagnosis was deemed too short by some physicians. A reduction in the follow-up protocol has been made by the study group, whereby the EUS examination at 3 months is suggested only for patients who have not undergone EUS previously. In future studies, EUS FNA could also be used to examine other tumour characteristics.

A potential pitfall of a wait-and-see approach is late detection of disease spread. This was the case in one patient in the present study who underwent surgery for rapid tumour progression, in whom peritoneal metastases were diagnosed during surgery. The sensitivity of CT, MRI, and DOTATATE PET–CT is known to be low for (small) peritoneal metastases.22,23 However, the optimal timing of adjuvant treatment for metastases in pNET is unknown, and treatment in the absence of radiologically measurable disease is usually not recommended. To truly evaluate the oncological safety of watchful waiting of pNET, longer follow-up is necessary. Nevertheless, it is important to report these short-term findings, because they give insight into the obstacles of implementation of new guidelines, as well as the pitfalls regarding treatment indication and sensitivity of imaging techniques. QoL was poorer at baseline in the study population than that of the reference population, but the results are too premature for conclusions to be drawn on the exact reason for this difference.

The authors further recommend improved patient support during the first years of watchful waiting. The PANDORA study is continuing to evaluate long-term outcomes of a wait-and-see approach for NF-pNETs no larger than 2 cm.
