Long-term effectiveness of eye movement desensitization and reprocessing in children and adolescents with medically related subthreshold post-traumatic stress disorder: a randomized controlled trial

Maya G. Meentken, Malindi van der Mheen, Ingrid M. van Beynum, Elisabeth W.C. Aendekerk, Jeroen S. Legerstee, Jan van der Ende, Riwka del Canho, Ramón J.L. Lindauer, Manon H.J. Hillegers, Willem A. Helbing, Henriette A. Mol, and Elisabeth M.W.J. Utens

Aims: Medical procedures and hospitalizations can be experienced as traumatic and can lead to post-traumatic stress reactions. Eye movement desensitization and reprocessing (EMDR) shows promising results but very few long-term studies have been published. Therefore, our aim was to test the long-term (8 months post-treatment) effectiveness of EMDR in children and adolescents with medically related subthreshold post-traumatic stress disorder (PTSD).

Methods and results: Seventy-four children (including 39 with congenital or acquired heart disease) aged 4–15 (M = 9.6 years) with subthreshold PTSD after previous hospitalization were included into a parallel group randomized controlled trial. Participants were randomized to EMDR (n = 37) or care-as-usual (CAU) (n = 37; medical care only). The primary outcome was PTSD symptoms of the child. Secondary outcomes were symptoms of depression and blood–injection–injury (BII) phobia, sleep problems, and health-related quality of life (HrQoL) of the child. Assessments of all outcomes were planned at baseline and 8 weeks and 8 months after the start of EMDR/CAU. We hypothesized that the EMDR group would show significantly more improvements on all outcomes over time. Both groups showed improvements over time on child’s symptoms of PTSD (only parent report), depression, BII phobia, sleep problems, and most HrQoL subscales. GEE analyses showed no significant differences between the EMDR group (nT2 = 33, nT3 = 30) and the CAU group (nT2 = 35, nT3 = 32) on the primary outcome. One superior effect of EMDR over time was found for reducing parent-reported BII phobia of the child.

Conclusion: EMDR did not perform better than CAU in reducing subthreshold PTSD up to 8 months post-treatment in previously hospitalized children. Possible explanations and clinical implications are discussed.
Introduction

Exposure to medical care is common during childhood and adolescence, especially for children and adolescents with congenital heart disease (ConHD). Medical care involves a variety of potentially traumatic events, such as painful diagnostics or medical treatments, surgical interventions, hospitalizations, life-threatening diagnoses, and separation of children from their caregivers. Subsequently, some children develop impairing emotional and behavioral difficulties, including post-traumatic stress. The long-term prevalence of post-traumatic stress disorder (PTSD) in children with ConHD is approximately 29% and roughly 11% after injury. Even more children (up to 38%) develop impairing symptoms of PTSD without meeting all criteria for a diagnostic disorder, called subthreshold PTSD. Subthreshold PTSD is associated with long-lasting impairment comparable to full diagnostic PTSD and accounts for a substantial future PTSD burden. Next to PTSD symptoms, 9–18% of adolescence with ConHD and 7–13% of critical ill children develop clinically relevant depressive symptoms. Furthermore, it has been found that 31% of children with ConHD show significant medical fears. Children with acquired heart disease also show more depressive and anxiety problems than children from the general population. Decreased health-related quality of life (HRQoL) is experienced in 25–60% of children with a ConHD and in up to 43% of children after paediatric intensive care unit admission. Sleep problems are also frequent, reported in up to 86% of children with common medical conditions and 79% of children with ConHD.

Attuned psychosocial interventions should be offered to reduce the wide diversity of symptoms. Meta-analyses show that eye movement desensitization and reprocessing (EMDR) is an effective psychotherapy to reduce PTSD symptoms in adults. EMDR has also been found to be effective in reducing depression, anxiety, and sleep problems, and in improving quality of life in adults. During EMDR, the vividness and emotional intensity of a distressing memory is reduced by concentrating on that memory while simultaneously reducing the vividness and emotional intensity of a distressing memory. This article specifically aims to investigate the long-term effectiveness of EMDR in children and adolescents with full diagnostic PTSD after various medically related potentially traumatic events should be studied in the future.

Keywords

EMDR • Congenital heart disease • Post-traumatic stress • Medical setting • Treatment outcome • Randomized controlled trial

Implications for practice

• This study provides preliminary evidence for the use of eye movement desensitization and reprocessing (EMDR) for blood–injection–injury phobia symptoms in children and adolescents after hospitalization.
• EMDR may be more effective for post-traumatic stress disorder (PTSD) symptoms when symptom severity is high.
• The effectiveness of EMDR for children and adolescents with full diagnostic PTSD after various medically related potentially traumatic events should be studied in the future.

Methods

The present study was a single-blinded RCT with two parallel groups comparing EMDR and care-as-usual (CAU). After written informed consent (from parents/guardians and children ≥12 years) and a positive screening for subthreshold PTSD, participating children were randomized using a 1:1 allocation ratio. A detailed version of the study protocol has previously been published. The study was approved by the Medical Ethics Committee of the Erasmus Medical Centre in the Netherlands, registered in the Dutch Trial Register (NTR5801), and designed conform
the CONSORT guidelines (Supplementary Information). The investigation conforms with the principles outlined in the Declaration of Helsinki.

Participants
Participants were continuously recruited from July 2016 until May 2018. Participants were recruited mainly at the Erasmus MC Sophia children’s hospital (paediatrics division and paediatric cardiology division) and the Maasstad hospital (paediatrics division) in Rotterdam, the Netherlands. Additional participants were recruited at the paediatric cardiology division of the Radboud UMC Nijmegen (RUMC), and nationally through the Dutch Association for patients with a congenital heart defect (Patiëntenvereniging Aangeboren Hartafwijkingen, PAH) and the Dutch non-profit organization Heartchild Foundation (Stichting Hartekind). We expected medium effects on PTSD symptoms based on a meta-analysis. A sample size of 78 participants was aimed to reach sufficient power.

Participating children were 4–15 years old and had been hospitalized at least 4 weeks but no more than 5 years ago for at least one night. The amount of psychological reactions in children might differ after acute versus chronic medical events. To encompass both groups we included children who had been hospitalized (i) at a paediatric cardiology department due to a congenital or acquired heart defect or (ii) after consultation at an ED due to acute injury or illness. Information on hospitalizations (number, data, length, and reason) was retrieved from the medical record by the research psychologist after possible participants were selected by the participating departments. For children included by the RUMC, PAH and Heartchild foundation, parent-report was used. We included children who experienced single and multiple hospitalizations with possible additional medical procedures.

Exclusion criteria were: (i) intellectual disability (IQ < 70) as assessed by previous standardized test or evaluated by a clinician; (ii) parental inability to read or write Dutch; (iii) diagnosis of a chronic illness for the ED subgroup; (iv) previous successful treatment for medically related PTSD; and (v) current psychological treatment.

Procedure
After having provided written informed consent, children and their parents completed a baseline measurement. The main goal of this measurement was to screen children for present post-traumatic stress symptoms using the Children’s Responses to Trauma Inventory (CRTI). Children who (i) fulfilled at least two of the three DSM-IV (Diagnostic and Statistical Manual of Mental Disorder, 4th edition) PTSD symptom criteria (i.e. re-experience, avoidance or hyperarousal) measured by the CRTI and/or (ii) had an above average score (i.e. >60th percentile) on the PTSD total score were included in the sample. Parents were excluded if they did not meet all criteria for a full diagnostic PTSD during the interview at the start of EMDR/CAU. Study data were collected and managed using GemsTracker.

A sample size of 78 participants was aimed to reach sufficient power. 

Post-traumatic stress symptoms (primary outcome)
The Dutch version of the Children’s Responses to Trauma Inventory (CRTI) provides a reliable and valid self-report (for ages 8–18) and parent-report (for ages 4–18) measure of the DSM-IV-TR PTSD symptoms. It contains 24 PTSD items divided into three symptom clusters of PTSD (intrusion, avoidance, and hyperarousal). The PTSD total score can range from 17 to 85, with a higher score indicating more problems. Internal consistency was .75, .90, and .88 for self-report and .87, .92, and .90 for parent-report at T1, T2 and T3, respectively (Cronbach’s z).

Additionally, semi-structured interviews were administered (only to participants meeting at least one of the two CRTI criteria mentioned before) to exclude children with a full diagnostic PTSD. The interview scores were not used for statistical analyses. We used the Clinician-Administered PTSD Scale for Children and Adolescents (CAPS-CA) for all participants aged 8–15 and the PTSD module of the DIPA for all parents of participants aged 4–7. The interviews were administered by the research psychologist (trained in both instruments) at the Erasmus MC Sophia Children’s Hospital.

Symptoms of depression (secondary outcome)
The Dutch Children’s Depression Inventory 2 (CDI-2; 8–21 years) has a parent version with 17 items on a 4-point Likert scale and a child version with 28 items on a 3-point Likert scale. The range of the total score of all items is 0 to 51 for parent report and 0 to 56 for child report. A higher score indicates more problems. Internal consistency was 0.81, 0.86, and 0.85 for self-report and 0.82, 0.84, and 0.86 for parent-report at T1, T2, and T3, respectively (Cronbach’s z).

Symptoms of blood–injection–injury phobia (secondary outcome)
The BII subscale of the Screen for Child Anxiety Related Emotional Disorders (SCARED-NL; 7–19 years) was used to measure child-report and parent-report of symptoms of BII phobia of the child. The BII subscale consists of 7 items and its total score ranges from 0 to 14 with a research psychologist. We stratified by trauma type (i.e. children who experienced a one-time hospitalization vs. children who experienced ≥2 hospitalizations or an additional medical procedure next to an one-time hospitalization) and age. Four fixed blocks (trauma type 1/age 4–11; trauma type 1/age 12–15; trauma type 2/age 4–11; trauma type 2/age 12–15) were used. Participants and therapists could not be blinded due to the nature of EMDR. However, the research psychologist and research assistants performing all measurements and the treating physician were blinded of group allocation (they had no access to files containing this information, nor were they informed). Participants were instructed to not share their group allocation with the research team nor treating physician. To plan post-treatment measurements, the independent research psychologist provided a start date for both groups falling within 2 weeks after the interview (for the EMDR group this was the date of the intake and for the CAU group a random date was picked).
Higher score indicating more problems. Internal consistency was 0.74, 0.69, and 0.73 for child-report and 0.71, 0.76, and 0.74 for parent-report at T1, T2, and T3, respectively (Cronbach’s α).

Sleep problems (secondary outcome)

Children filled out the Dutch Sleep Self Report (SSR; 23 items; 7–12 years) and parents filled out the parallel parent version called Child Sleep Habits Questionnaire (CSHQ; 35 items; 4–10 years). Maximum total scores are 69 for the SSR and 99 for the CSHQ. Again, a higher score indicates more sleep problems. Internal consistency was 0.73, 0.80, and 0.81 for the SSR and 0.81, 0.83, and 0.82 for the CSHQ at T1, T2, and T3, respectively (Cronbach’s α).

Health-related quality of life (secondary outcome)

The TNO-AZL Questionnaires for Children’s Health-Related Quality of Life (TACQOL; 8–15 years) provides a reliable and valid description of health-related quality of life. Based on the 63 items, seven subscales can be computed, namely: body, motor, autonomy, cognition, social, positive emotions, and negative emotions. In contrast to the other questionnaires used, a higher score on the TACQOL subscales indicates better HrQoL. Cronbach’s α on most subscales ranged from 0.66–0.81, 0.62–0.82, and 0.66–0.83 for self-report and from 0.62–0.88, 0.66–0.90, and 0.74–0.92 for parent report at T1, T2, and T3, respectively. The only poor to inadequate internal consistencies were found for the subscale autonomy: Cronbach’s α was 0.66, 0.62, and 0.32 for self-report and 0.59, 0.52, and 0.44 for parent report at T1, T2, and T3, respectively.

Demographics

Demographic information was gathered with the general scale of the Rotterdam’s Quality of Life Interview. Furthermore, we checked for the experience of non-medical stressful life events using the life events scale of the Cognitive Emotion Regulation Questionnaire.

Intervention

The intervention was provided using the Dutch version of the standard EMDR protocol for children. Young children or children with pre-verbal memories were treated with the modified protocol by Lovett. In accordance to the standard protocol, children could make a drawing of their distressing medical experiences during therapy to facilitate a mental representation of the memory. All EMDR sessions took place at the Erasmus MC Sophia Children’s Hospital in Rotterdam, the Netherlands and were provided by five licensed and experienced clinical psychologists. Sessions were planned once a week and lasted approximately 50 min. Parents were allowed to be present during the sessions when the child agreed on this with the therapist but were instructed not to interfere with the session. EMDR treatment was completed when Subjective Units of Distress of all selected memories regarding the medical trauma were zero. Only when this was impossible, EMDR treatment was ended when positive cognitions were established (rated by the child) and child, parents, and therapist agreed that PTSD symptoms had sufficiently decreased. Therapists reported all details and dates to the independent researcher who documented this in protected files.

Children in the CAU (care-as-usual control) group also received standard medical care and standard study-related procedures (psychological screening and interview). They did not receive EMDR or any other form of psychotherapy.

Treatment integrity

Treatment integrity was ensured by providing regular supervision by an EMDR Europe consultant (licensed EMDR supervisor) and by rating all videotaped or documented sessions of 10 randomly chosen children (27%) as to adherence to the protocol. Rating was done by a research psychologist trained in the EMDR protocol and by two trained Master students in psychology (supervised by the aforementioned research psychologist) using an EMDR-specific treatment integrity checklist (16 items). A total score ranging from 0 to 16 can be computed from the checklist with a higher score indicating higher protocol adherence. All total scores given independently by all three raters were ranging between 13 and 16, indicating high agreement between the raters and high treatment integrity.

Statistical analyses

We used t-tests and χ² tests where appropriate to test differences in baseline characteristics between the EMDR and CAU groups.

We conducted Generalized Estimating Equations (GEE) with an unstructured correlation matrix to examine the effect of the intervention on all outcomes. The GEE analysis accounted for all assessments and were performed using intention-to-treat principles. Every outcome was analysed separately. We included time of the assessments in every GEE analyses and added the interaction between group (EMDR vs. CAU) to test for the effects of the intervention. Wald χ² tests indicated whether the interactions were significant. If interactions were significant, we conducted subsequent analyses in which we included age, gender and whether the child had experienced ≥1 other non-medical stressful life event as covariates. For explorative analyses, we ran the same GEE analyses again separated by group (cardio vs. ED).

P-values of <0.05 were considered significant. Cohen’s d effect sizes were computed as the interaction effect of group by time multiplied by the number of weeks at the endpoint divided by the pooled standard deviations of the outcomes at T1. GEE accommodates missing data. SPSS version 24.0 was used for all statistical analyses.

Results

General characteristics

We randomized 74 children to the EMDR (n = 37) and CAU (n = 37) group (see Figure 1). There were no significant differences between both groups on demographic baseline variables (see Table 1). The average number of EMDR sessions received was M = 3.33 (SD = 1.95; range 1–9). Every child in the EMDR group was treated for at least one medically related distressing memory. The follow-up assessments took place M T2 = 9.75 (SD = 2.28) weeks and M T3 = 8.15 (SD = 0.57) months after the start of EMDR/CAU. The time between baseline and follow-up assessments was not different for both groups. Two participants of the CAU group reported the start of mental health care after the 8 weeks follow-up. No study-related adverse events were communicated.

Long-term effectiveness of EMDR

Primary outcome

Child report: The interaction of group by time was not significant for PTSD symptoms reported by the child (see Table 2). The improvement over time was also not significant for child-reported PTSD symptoms (b = -0.02, P = 0.641).

Parent report: The interaction of group by time was not significant for parent-reported PTSD symptoms of the child neither (see Table 2). However, the improvement of child PTSD symptoms over time reported by parents was significant (b = -0.20, P = 0.000).
Figure 1 CONSORT flow chart.

aDid not show up for last sessions and did not answer to calls nor e-mails. bTwo participants of the CAU group started mental health services after T2. Participation rate: 100/(total non-participants + informed consents)
Secondary outcomes

Child report: There were no significant interactions of group by time for any of the secondary child-report outcomes (see Table 2). Both groups showed improvements on the secondary outcomes over time: depressive symptoms ($b = -0.06, P = 0.000$), symptoms of Blf phobia ($b = -0.05, P = 0.000$), sleep problems ($b = -0.04, P = 0.020$), HrQoL-body ($b = 0.07, P = 0.000$), HrQoL-Motor ($b = 0.03, P = 0.022$), HrQoL-Autonomy ($b = 0.02, P = 0.034$), HrQoL-Cognitive ($b = 0.04, P = 0.004$), HrQoL-Positive Emotions ($b = 0.03, P = 0.000$), and HrQoL-Negative Emotions ($b = 0.02, P = 0.004$). The improvement over time was not significant for child-reported HrQoL-Social ($b = 0.03, P = 0.053$).

Parent-report: One interaction of group by time was significant for parent-report (see Table 2). That is, EMDR was more effective than CAU in reducing parent-reported Blf-phobia of the child. This interaction was still significant when controlling for age, gender, and other non-medical stressful life events ($b = -0.03, P = 0.033$). Furthermore, both groups showed improvements on the following secondary outcomes over time: depressive symptoms ($b = -0.04, P = 0.009$), symptoms of Blf phobia ($b = -0.03, P = 0.000$), sleep problems ($b = -0.07, P = 0.000$), HrQoL-body ($b = 0.03, P = 0.037$), HrQoL-Cognitive ($b = 0.03, P = 0.045$), HrQoL-Social ($b = 0.03, P = 0.001$), and HrQoL-Negative Emotions ($b = 0.03, P = 0.000$). The improvement over time was not significant for parent-reported HrQoL-Motor ($b = 0.02, P = 0.083$), HrQoL-Autonomy ($b = 0.01, P = 0.108$), and HrQoL-Positive Emotions ($b = 0.00, P = 0.543$).

Explorative analyses

One interaction of group by time was significant when running the GEE analyses by group. For the cardiology group, EMDR was more effective than CAU in reducing parent-reported Blf-phobia of the child ($b = -0.06, P = 0.000$). The same interaction was not significant.

Discussion

The present RCT examined the long-term effectiveness of EMDR on PTSD symptoms and other psychological complaints in children with medically related subthreshold PTSD. The results show that most outcomes improved over time with one significant difference between the EMDR and CAU group.

We found preliminary evidence that EMDR was significantly superior than CAU in reducing parent-reported symptoms of children’s BII-phobia. It is possible that this was a random finding. However, it is supported by earlier research that has found EMDR to be effective in reducing dental phobia.49,50 This could have high clinical relevance as phobic people tend to avoid the source of their fear. Consequently, children with symptoms of BII-phobia might avoid medical treatment. This is especially concerning considering the necessity of continuous medical checkups for children affected by a heart disease. By reducing BII phobia symptoms, EMDR contributes to medically necessary adherence. Future research is needed before validated statements can be made. This is also true considering the fact that we only found a superior long-term effect for parent-reported BII-phobia of the child.

On self-report, both the EMDR and the CAU group showed improvement. Nevertheless, it has been argued that parent report might identify recovery from anxiety symptoms better than child report.51 Unfortunately, we could not control for parental psychopathology, which has been found to influence parent report of the child’s mental health, as we did not measure parental psychopathology.52 Our results regarding the effectiveness of EMDR in treating BII phobia symptoms warrants further research in this area. Especially as the effect of EMDR on BII phobia seemed to be present in the cardiology group only.

Our results that EMDR was not superior than CAU in reducing symptoms of PTSD, depression, and sleep problems and in improving HRQoL over time are not in line with earlier studies with >6 months post-treatment follow-ups.23–25 In our view, there are five major differences between the EMDR and CAU group.

First, participation rate was low in our sample (26%, see Figure 1), it is possible that some participants in the CAU group might have arranged psychosocial treatment for themselves during the study period. However, participants were asked friendly to communicate any contact with a mental health specialist during the study period. Two children of the CAU group started EMDR elsewhere between both follow-up assessments. Second, we did not measure parental mental health nor did parents receive treatment. Research suggests that parental mental health is a strong predictor for child PTSD symptoms and that involving parents in the treatment of their child might be beneficial.59–62 Third, it is likely that the effectiveness of EMDR specifically for children with medically related subthreshold PTSD. It is unclear to which extent our findings are generalizable to other kind of traumas or to children with full diagnostic PTSD.

Strengths and limitations

While this study is the first to evaluate the effectiveness of EMDR in a relatively large sample of children with medically related subthreshold PTSD recruited throughout the Netherlands, including a broad age range, multi-informant outcomes, high treatment integrity, and single-blind randomization, some limitations must be considered. First, it is possible that some participants in the CAU group might have arranged psychosocial treatment for themselves during the study period. However, participants were asked friendly to communicate any contact with a mental health specialist during the study period. Two children of the CAU group started EMDR elsewhere between both follow-up assessments. Second, we did not measure parental mental health nor did parents receive treatment. Research suggests that parental mental health is a strong predictor for child PTSD symptoms and that involving parents in the treatment of their child might be beneficial.59–62 Third, it is likely that the effectiveness of EMDR specifically for children with medically related subthreshold PTSD. It is unclear to which extent our findings are generalizable to other kind of traumas or to children with full diagnostic PTSD.

Acknowledgements

First, we gratefully want to thank all participants, their parents/guardians and all involved therapists. Furthermore, we want to thank all
participating departments and organizations for their efforts in recruiting participants.

Funding
This work was supported by Innovatiefonds Zorgverzekeraars, Stichting Hartekind & Vereniging EMDR Nederland. The funding institutions had no involvement in the study design; the collection, analysis, and interpretation of data; the writing of the report; or the decision to submit the manuscript for publication.
